

Autoignition of the hydrogen and oxygen-nitrogen combinations mixture at 650K

Ewelina Zaremba LiK Metody komputerowe w spalaniu
September 15, 2017

Scope

The scope of this examination was to observe the changes of parameters describing autoignition, related to the ϕ ratio value, and finding a relation between detonation cell width and induction time.

This parameters are:

- Induction time [s]
- Chapman - Jouget speed [m/s]
- Exothermic time [s]
- Pressure post shock [Pa]
- Temperature post shock [K]
- Final temperature [K]
- Effective activation energy

Assumptions

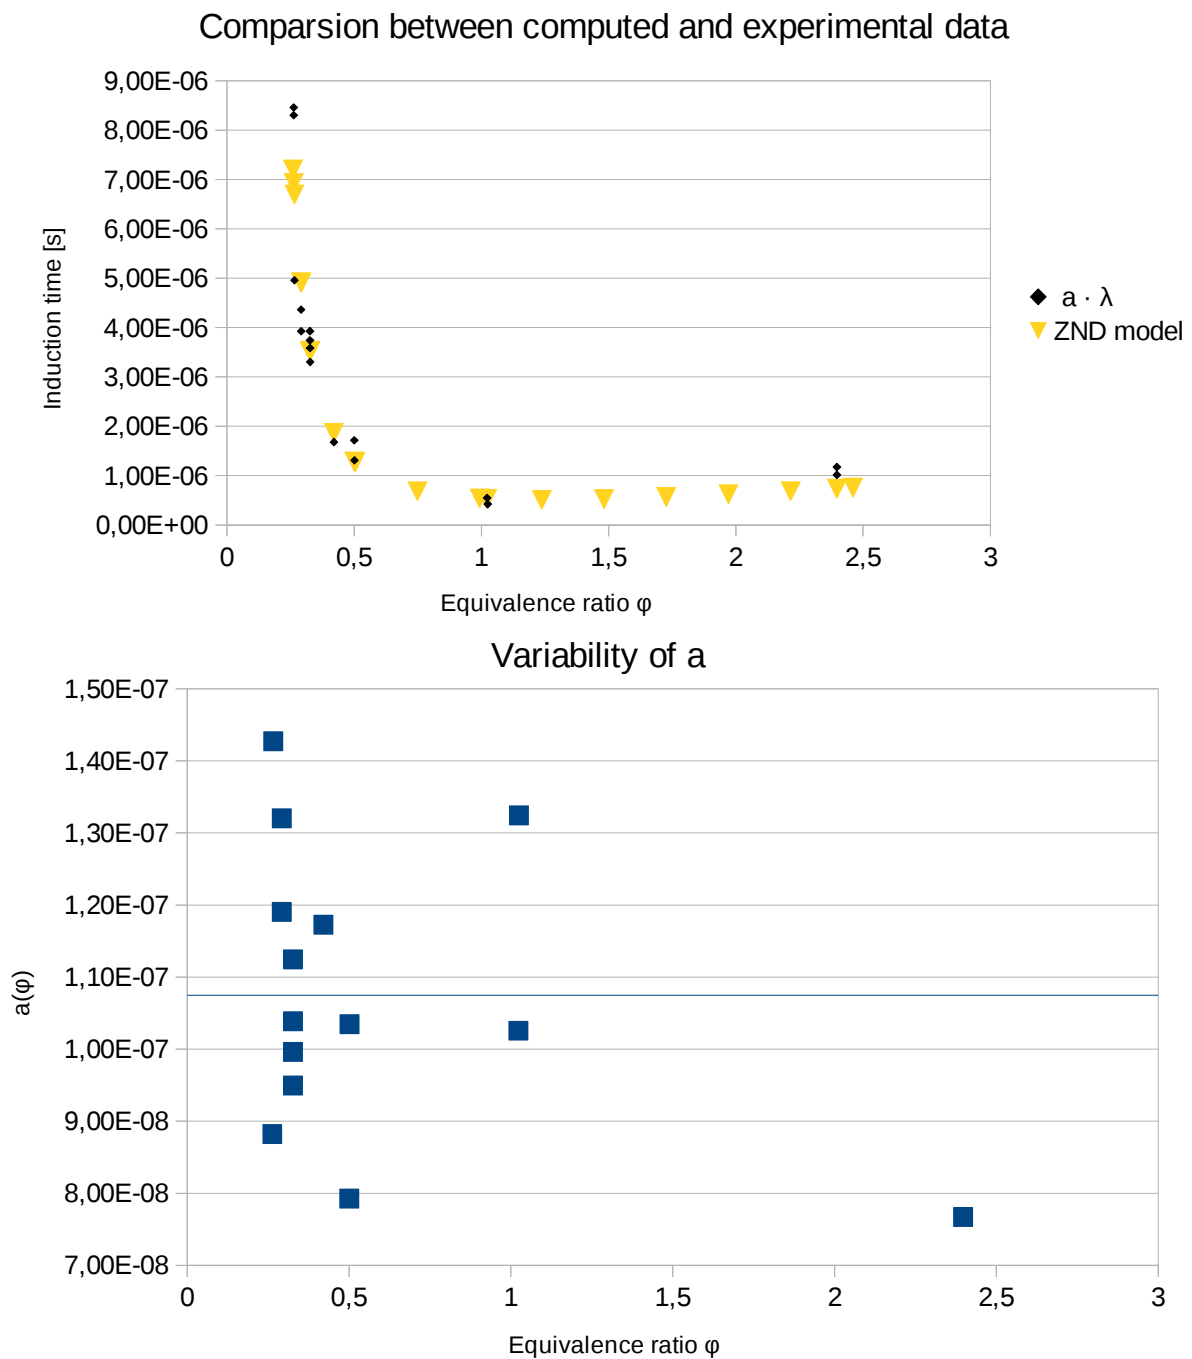

The constant molar sum approach was conducted (it could also be the constant mass sum approach). Calculations were zero-dimensional.

Mathematical model

Build-in Cantera functions and SDToolbox Matlab scripts were used. ZND model was used. As one of point of this work was to find relation between cell width and induction time, some computation was made. Hypothesis is $t_{ind}(\phi) = a \cdot \lambda(\phi)$. Using simple math: $a(\phi) = t_{ind}(\phi) / \lambda(\phi)$. a is function of ϕ , because of many possible errors, like determining cell size precision. For this linear equation an estimator of constant **a** was a mean.

Results

As it is shown on the plots below, the results were obtained in line with expectations.

Mean a value is $1,074\text{e-}7[\text{s/m}]$.

Coefficient of variation is 0,18.

Summary

Our x axis on every plot represents phi ratio.

Experimental data matches well for computation model.

Extremes for most computed plots are for $\phi = 1$.

Characteristics of final temperature and maximum pressure results from the different proportions of ingredients.

Effective activation energy drops fast for ϕ in (0.25, 0.5) as like exothermic time.
